## Abstract

We present an approach that exploits hierarchical Recurrent Neural Networks (RNNs) to tackle the video captioning problem, i.e., generating one or multiple sentences to describe a realistic video. Our hierarchical framework contains a sentence generator and a paragraph generator. The sentence generator produces one simple short sentence that describes a specific short video interval. It exploits both temporal- and spatial-attention mechanisms to selectively focus on visual elements during generation. The paragraph generator captures the inter-sentence dependency by taking as input the sentential embedding produced by the sentence generator, combining it with the paragraph history, and outputting the new initial state for the sentence generator. We evaluate our approach on two large-scale benchmark datasets: YouTubeClips and TACoS-MultiLevel. The experiments demonstrate that our approach significantly outperforms the current state-of-the-art methods with BLEU@4 scores 0.499 and 0.305 respectively.

## 1. Introduction

In this paper, we consider the problem of video captioning, i.e. generating one or multiple sentences to describe the content of a video. The given video could be as general as those uploaded to YouTube, or it could be as specific as cooking videos with fine-grained activities. This ability to generate linguistic description for unconstrained video is important because not only it is a critical step towards machine intelligence, but also it has many applications in daily scenarios such as video retrieval, automatic video subtitling, blind navigation, etc. Figure 1 shows some example sentences generated by our approach.

The video captioning problem has been studied for over one decade ever since the first rule-based system on describ-

ing human activities with natural language [23]. In a very limited setting, Kojima *et al.* designed some simple heuristics for identifying video objects and a set of rules for producing verbs and prepositions. A sentence is then generated by filling predefined templates with the recognized parts of speech. Following their work, several succeeding approaches [26, 20, 21, 15, 3] applied similar rule-based systems to datasets with larger numbers of objects and events, in different tasks and scenarios. With *ad hoc* rules, they manually establish the correspondence between linguistic terms and visual elements, and then analyze the relations among the visual elements to generate sentences. Among these methods, the most complex rule-based system [3] supports a vocabulary of 118 lexical entries (including 48 verbs and 24 nouns).

To eliminate the tedious effort of rule engineering when the problem scales, some recent methods train statistical models for lexical entries, either in a fully [10, 14, 24, 41] or weakly [36, 35, 57, 54] supervised fashion. The statistical models of different parts of speech usually have different mathematical representations and training strategies (*e.g.*, [14, 24]). With most of the manual effort gone, the training process exposes these methods to even larger datasets (*e.g.*, YouTubeClips [6] and TACoS-MultiLevel [35]) which contain thousands of lexical entries and dozens of hours of video. As a result, the video captioning task becomes much more challenging, and the generation performance of these methods is usually low on these large-scale datasets.

Since then, inspiring results have been achieved by a recent line of video-captioning work [11, 47, 46, 33, 53, 55] which benefits from the rapid development of deep neural networks, especially Recurrent Neural Network (RNN). Applying RNN to translating visual sequence to natural language is largely inspired by the recent advances in Neural Machine Translation (NMT) [1, 42] in the natural language processing community. The idea is to treat the image sequence of a video as the “source text” and the corresponding caption as the target text. Given a sequence of deep con-

\*This work was done while the author was at Baidu.

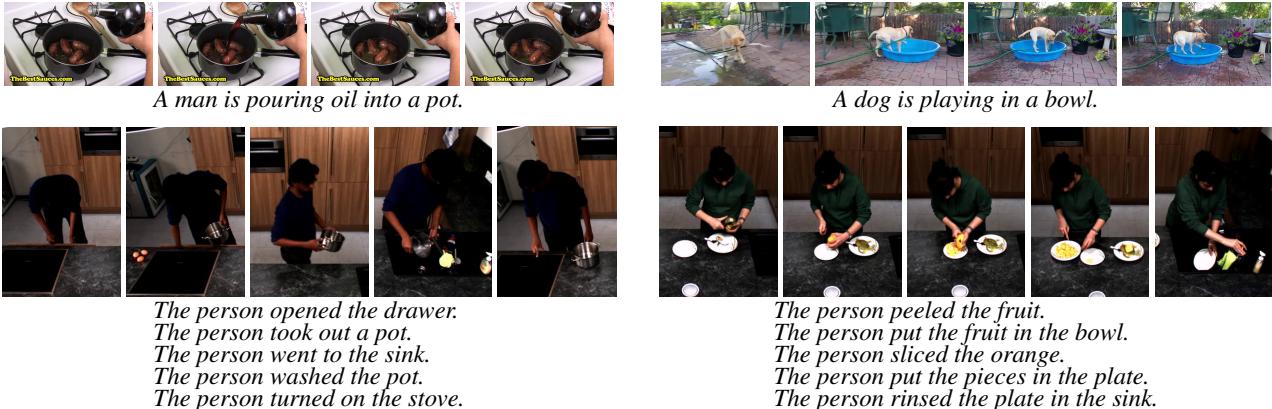

Figure 1. Some example sentences generated by our approach. The first row shows examples trained on YouTubeClips, where only one sentence is generated for each video. The second row shows examples trained on TACoS-MultiLevel, where paragraphs are generated.

volutional features (*e.g.*, VggNet [39], C3D [44], *etc.*) extracted from video frames, a compact representation of the video is first obtained by simple average pooling [47, 33], weighted average pooling with an attention model [55], or taking the last output from an RNN encoder which summarizes the feature sequence [11, 46, 53]. Then an RNN decoder accepts this compact representation and outputs a sentence of a variable length. While good results were obtained, these methods only focus on generating a single sentence for a short video clip. It still remains largely unexplored how to generate multiple sentences or a paragraph for a long video.

The motivation of generating multiple sentences is that most videos depict far more than just one event. However, the current state-of-the-art RNNs still lack the ability to generate a single very long sentence to convey rich semantics. Thus using only one short sentence to describe a semantically rich video usually yields uninformative and even boring results. For example, instead of saying *the person sliced the potatoes, cut the onions into pieces, put the onions and potatoes into the pot, and turned on the stove*, a method that is only able to produce one short sentence would probably say *the person is cooking*.

Inspired by the recent progress of document modeling [27, 28] in natural language processing, we propose a hierarchical-RNN framework for describing a long video with a paragraph consisting of multiple sentences. The idea behind our hierarchical framework is that we want to exploit the temporal dependency among sentences in a paragraph, so that when producing the paragraph, the sentences are not generated independently. Instead, the generation of one sentence might be affected by the semantic context provided by the previous sentences. For example, in a video of cooking dishes, a sentence *the person peeled the potatoes* is more likely to occur, than the sentence *the person turned on the stove*, after the sentence *the person took out*

*some potatoes from the fridge*. Towards this end, our hierarchical framework consists of two generators, *i.e.* a sentence generator and a paragraph generator, both of which use recurrent layers for language modeling. At the low level, the sentence generator produces single short sentences that describe specific time intervals and video regions. We exploit both temporal- and spatial-attention mechanisms to selectively focus on visual elements when generating a sentence. The embedding of the generated sentence is encoded by the output of the recurrent layer. At the high level, the paragraph generator takes the sentential embedding as input, and uses another recurrent layer to output the paragraph state, which is then used as the new initial state of the sentence generator (see Section 3). Figure 2 illustrates our overall framework. We evaluate our approach on two public datasets: YouTubeClips [6] and TACoS-MultiLevel [35]. We show that our approach significantly outperforms other state-of-the-art methods on both datasets.

## 2. Related Work

**Neural Machine Translation.** The methods for NMT [18, 9, 1, 42, 27, 28] in computational linguistics generally follow the encoder-decoder paradigm. An encoder maps the source sentence to a fixed-length feature vector in the embedding space. A decoder then conditions on this vector to generate a translated sentence in the target language. On top of this paradigm, several improvements were proposed. Bahdanau *et al.* [1] proposed a soft attention model to do alignment during translation, so that their approach is able to focus on different parts of the source sentence when generating different translated words. Li *et al.* [27] and Lin *et al.* [28] employed hierarchical RNN to model the hierarchy of a document. Our approach is much similar to a neural machine translator with a simplified attention model and a hierarchical architecture.

**Image captioning with RNNs.** The first attempt of visual-

to-text translation using RNNs was seen in the work of image captioning [30, 22, 19, 49, 8], which can be treated as a special case of video captioning when each video has a single frame and no temporal structure. Because of this, image captioning only requires computing object appearance features, but not action/motion features. The amount of data handled by an image captioning method is much (dozens of times) less than that handled by a video captioning method. The overall structure of an image captioner (instance-to-sequence) is also usually simpler than that of a video captioner (sequence-to-sequence). While there have been quite a few large-scale datasets with high-quality annotation for image captioning (*e.g.*, Flickr 30K [56] and MS COCO [29]), there are fewer for video captioning.

**Video captioning with RNNs.** The very early video captioning method [47] based on RNNs extends the image captioning methods by simply average pooling the video frames. Then the problem becomes exactly the same as image captioning. However, this strategy works only for short video clips where there is only one major event, usually appearing in one video shot from the beginning to the end. To avoid this issue, more sophisticated ways of encoding video features were proposed in later work, using either a recurrent encoder [11, 46, 53] or an attention model [55]. Our sentence generator is closely related to Yao *et al.* [55], in that we also use attention mechanism to selectively focus on video features. One difference between our framework and theirs is that we additionally exploit spatial attention. The other difference is that after weighing video features with attention weights, we do not condition the hidden state of our recurrent layer on the weighted features (Section 3.2). We found in the experiments that our choice yielded much better results.

### 3. Hierarchical RNN for Video Captioning

Our approach stacks a paragraph generator on top of a sentence generator. The sentence generator is built upon 1) a Recurrent Neural Network (RNN) for language modeling, 2) a multimodal layer [30] for integrating information from different sources, and 3) an attention model [55, 1] for selectively focusing on the input video features. The paragraph generator is simply another RNN which models the inter-sentence dependency. It receives the compact sentential representation encoded by the sentence generator, combines it with the paragraph history, and outputs a new initial state for the sentence generator. The RNNs exploited by the two generators incorporate the *Gated Recurrent Unit* (GRU) [9] which is a simplification of the Long Short-Term Memory (LSTM) architecture [16]. In the following, we first briefly review the RNN with the GRU (or the *gated RNN*), and then describe our framework in details.

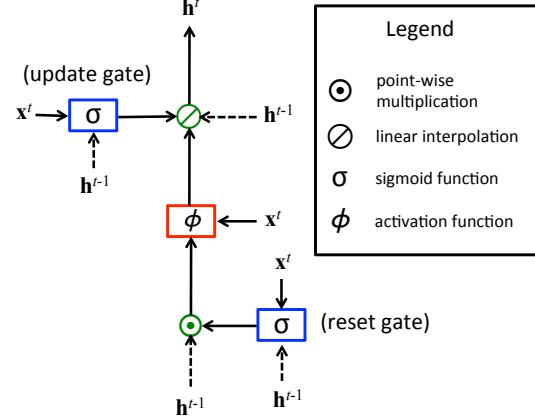

Figure 3. A diagram of a Gated Recurrent Unit (GRU).

#### 3.1. Gated Recurrent Unit

A simple RNN [12] can be constructed by adding feedback connections to a feedforward network that consists of three layers: the input layer  $\mathbf{x}$ , the hidden layer  $\mathbf{h}$ , and the output layer  $\mathbf{y}$ . The network is updated by both the input and the previous recurrent hidden state as follows:

$$\begin{aligned}\mathbf{h}^t &= \phi(\mathbf{W}_h \mathbf{x}^t + \mathbf{U}_h \mathbf{h}^{t-1} + \mathbf{b}_h) && \text{(hidden state)} \\ \mathbf{y}^t &= \phi(\mathbf{U}_y \mathbf{h}^t + \mathbf{b}_y) && \text{(output)}\end{aligned}$$

where  $\mathbf{W}$ ,  $\mathbf{U}$  and  $\mathbf{b}$  are weight matrices and biases to be learned, and  $\phi(\cdot)$  are element-wise activation functions.

While the simple RNN is able to model temporal dependency for a small time gap, it usually fails to capture long-term temporal information. To address this issue, the GRU [9] is designed to adaptively remember and forget the past. Inside the unit, the hidden state is modulated by non-linear gates (Figure 3). Specifically, let  $\odot$  denote the element-wise multiplication of two vectors, the GRU computes the hidden state  $\mathbf{h}$  as:

$$\begin{aligned}\mathbf{r}^t &= \sigma(\mathbf{W}_r \mathbf{x}^t + \mathbf{U}_r \mathbf{h}^{t-1} + \mathbf{b}_r) && \text{(reset gate)} \\ \mathbf{z}^t &= \sigma(\mathbf{W}_z \mathbf{x}^t + \mathbf{U}_z \mathbf{h}^{t-1} + \mathbf{b}_z) && \text{(update gate)} \\ \tilde{\mathbf{h}}^t &= \phi(\mathbf{W}_h \mathbf{x}^t + \mathbf{U}_h (\mathbf{r}^t \odot \mathbf{h}^{t-1}) + \mathbf{b}_h) \\ \mathbf{h}^t &= \mathbf{z}^t \odot \mathbf{h}^{t-1} + (1 - \mathbf{z}^t) \odot \tilde{\mathbf{h}}^t && \text{(hidden state)}\end{aligned}$$

where  $\sigma(\cdot)$  are element-wise Sigmoid functions. The reset gate  $\mathbf{r}$  determines whether the hidden state wants to drop any information that will be irrelevant in the future. The update gate  $\mathbf{z}$  controls how much information from the previous hidden state will be preserved for the current state. During the training of a gated RNN, the parameters can be estimated by Backpropagation Through Time (BPTT) [52] as in traditional RNN architectures.

#### 3.2. Sentence Generator

The overall structure of our hierarchical RNN is illustrated in Figure 2. The sentence generator operates at every

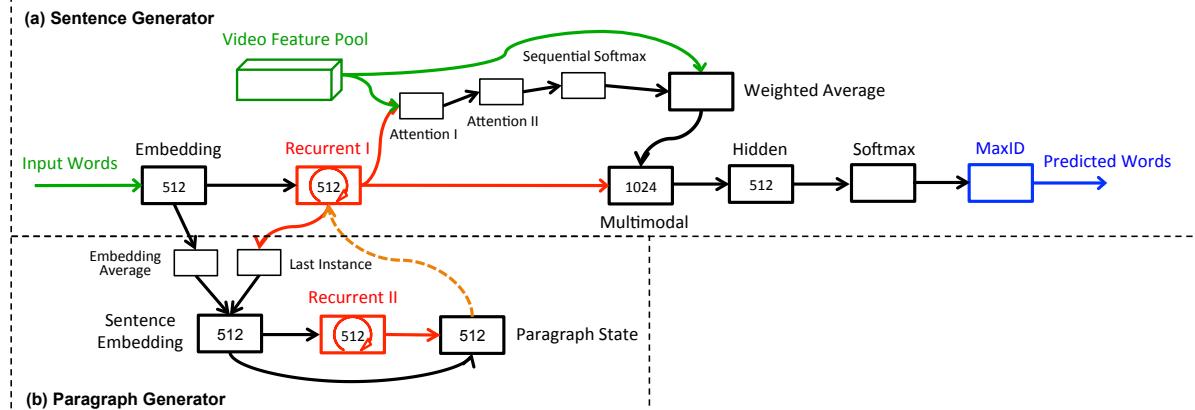

Figure 2. Our hierarchical RNN for video captioning. Green denotes the input to the framework, blue denotes the output, and red denotes the recurrent components. The orange arrow represents the reinitialization of the sentence generator with the current paragraph state. For simplicity, we only draw a single video feature pool in the figure. In fact, both appearance and action features go through a similar attention process before they are fed into the multimodal layer.

time step when a one-hot input (1-of- $N$  encoding, where  $N$  is the vocabulary size) arrives at the embedding layer. The embedding layer converts the one-hot vector to a dense representation in a lower dimensional space by multiplying it with an embedding table ( $512 \times N$ ), of which each row is a word embedding to be learned. The resulting word embedding is then input to our first RNN, *i.e.*, the recurrent layer I. This gated recurrent layer has 512 dimensions and acts similarly to those that are commonly employed by a variety of image/video captioning methods (*e.g.*, [46, 30, 55]), *i.e.*, modeling the syntax of a language. It updates its hidden state every time a new word arrives, and encodes the sentence semantics in a compact form up to the words that have been fed in. We set the activation function  $\phi$  of this recurrent layer to be the Rectified Linear Unit (ReLU) [32], since it performs better than non-linear activation functions such as the Sigmoid according to our observation.

As one branch, the output of the recurrent layer I is directed to the attention layers to compute attention weights for the features in the video feature pool. Our attention model is inspired by the recent soft-alignment method that has been successfully applied in the context of Neural Machine Translation (NMT) [1], and was later adapted to video captioning by Yao *et al.* [55]. The difference between our model and the one used by Yao *et al.* is that their model only focuses on temporal attention. We additionally include spatial attention by computing features for multiple image patches at different locations on a video frame and pool the features together. This simple improvement is important when objects are small and difficult to be localized on some datasets (*e.g.* TACoS-MultiLevel [35]). In this case, whole-frame-based video features will fail to capture the object information and multiple object proposals are needed for good performance (see Section 5.2 for details). Let the fea-

tures in the pool be denoted as  $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{KM}\}$ , where  $M$  is the video length and  $K$  is the number of patches on each frame. We want to compute a set of weights  $\{\beta_1^t, \beta_2^t, \dots, \beta_{KM}^t\}$  for these features at each time step  $t$  such that  $\sum_{m=1}^{KM} \beta_m^t = 1$ . To do so, we first compute an attention score  $q_m^t$  for each frame  $m$ , conditioning on the previous hidden state  $\mathbf{h}^{t-1}$ :

$$q_m^t = \mathbf{w}^\top \phi(\mathbf{W}_q \mathbf{v}_m + \mathbf{U}_q \mathbf{h}^{t-1} + \mathbf{b}_q)$$

where  $\mathbf{w}$ ,  $\mathbf{W}_q$ ,  $\mathbf{U}_q$ , and  $\mathbf{b}_q$  are the parameters shared by all the features at all the time steps, and  $\phi$  is set to the element-wise Scaled Hyperbolic Tangent (stanh) function [25]:  $1.7159 \cdot \tanh(\frac{2x}{3})$ . The above computation is performed by the attention layers I and II in Figure 2(a), where the attention layer I projects the feature  $\mathbf{v}$  and the hidden state  $\mathbf{h}$  into a lower dimensional space whose dimension can range from 32 to 256. The attention layer II then further compresses the activation of the projected vector into a scalar, one for each feature. After this, we set up a sequential softmax layer to get the attention weights:

$$\beta_m^t = \exp(q_m^t) / \sum_{m'=1}^{KM} \exp(q_{m'}^t)$$

Finally, a single feature vector is obtained by weighted averaging:  $\mathbf{u}^t = \sum_{m=1}^{KM} \beta_m^t \mathbf{v}_m$ . The above process is a sophisticated version of the temporal mean pooling. It allows the sentence generator to selectively focus on a subset of the features during generation. Note that while only one feature channel is shown in Figure 2(a), our sentence generator in fact pumps features of several channels through the same attention process. Each feature channel has a different set of weights and biases to be learned. In our experiments, we employ two feature channels, one for object appearance and the other for action/motion. (Section 5.2).

After the attention process, the weighted sums of the video features are fed into the multimodal layer which has 1024 dimensions. The multimodal layer also receives the output of the recurrent layer I, thus connecting the vision component with the language model. Suppose we have two video feature channels, of which the weighted features output by the attention model are  $\mathbf{u}_o^t$  and  $\mathbf{u}_a^t$  respectively. The multimodal layer maps the two features, together with the hidden state  $\mathbf{h}^t$  of the recurrent layer I, into a 1024 dimensional feature space and add them up:

$$\mathbf{m}^t = \phi(\mathbf{W}_{m,o}\mathbf{u}_o^t + \mathbf{W}_{m,a}\mathbf{u}_a^t + \mathbf{U}_m\mathbf{h}^t + \mathbf{b}_m)$$

where  $\phi$  is set to the element-wise stanh function. To reduce overfitting, we add dropout [40] with a drop rate of 0.5 to this layer.

The multimodal layer is followed by a hidden layer and a softmax layer (see Figure 2(a)), both with the element-wise stanh function as their activation functions. The hidden layer has exactly the same dimension 512 with the word embedding layer, and the softmax layer has a dimension that is equal to the size of the vocabulary which is dataset-dependent. Inspired by the transposed weight sharing scheme recently proposed by Mao *et al.* [31], we set the projection matrix from the hidden layer to the softmax layer as the transpose of the word embedding table. It has been shown that this strategy allows the use of a word embedding layer with a much larger dimension due to the parameter sharing, and helps regularize the word embedding table because of the matrix transpose. As the final step of the sentence generator, the maxid layer picks the index that points to the maximal value in the output of the softmax layer. The index is then treated as the predicted word id. Note that during test, the predicted word will be fed back to the sentence generator again as the next input word. While in the training, the next input word is always provided by the annotated sentence.

### 3.3. Paragraph Generator

The sentence generator above only handles one single sentence at a time. For the first sentence in the paragraph, the initial state of the recurrent layer I is set to all zeros, *i.e.*,  $\mathbf{h}^0 = \mathbf{0}$ . However, any sentence after that will have its initial state conditioned on the semantic context of all its preceding sentences. This semantic context is encoded by our paragraph generator.

During the generation of a sentence, an embedding average layer (see Figure 2(b)) accumulates all the word embeddings of the sentence and takes the average to get a compact embedding vector. The average strategy is inspired by the QA embedding [5] in which questions and answers are both represented as a combination of the embeddings of their individual words and/or symbols. We also take the last state of the recurrent layer I as a compact representation for the

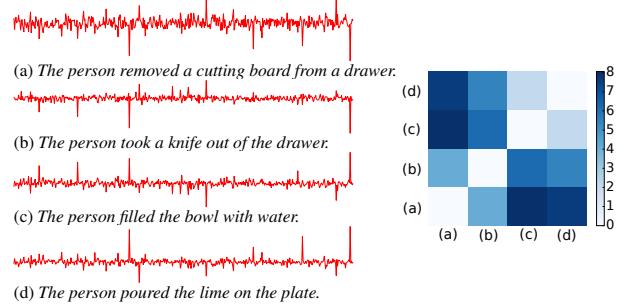

Figure 4. Left column: four examples of our learned sentence embeddings. Each 512 dimensional embedding is drawn as a red curve. Right column: the Euclidean distance between every two embeddings. A small distance indicates that two sentences have similar meanings. Notice how (a) and (b) are similar to each other due to sharing common keywords. Also note that even though (c) and (d) are quite different literally, our framework learns similar semantics for them from the video features.

sentence, following the idea behind the Encoder-Decoder framework [9] in NMT. After that, the averaged embedding and the last recurrent state are concatenated together, fully connected to the sentence embedding layer (512 dimensions) with the stanh as the activation function. We treat the output of the sentence embedding layer as the final sentence representation. Some examples of learned sentence embeddings are shown in Figure 4. It can be seen that our sentence embedding layer indeed encodes useful sentential information which is crucial for the later paragraph modeling.

The sentence embedding layer is linked to our second gated RNN (see Figure 2(b)). The recurrent layer II operates whenever a full sentence goes through the sentence generator and the sentence embedding is produced by the sentence embedding layer. Thus the two recurrent layers are asynchronous: while the recurrent layer I keeps updating its hidden state at every time step, the recurrent layer II only updates its hidden state when a full sentence has been processed. The recurrent layer II encodes the paragraph semantics in a compact form up to the sentences that have been fed in. Finally, we set up a paragraph state layer to combine the hidden state of the recurrent layer II and the sentence embedding. This paragraph state is used as the initial hidden state when the recurrent layer I is reinitialized for the next sentence. It essentially provides the sentence generator with the paragraph history so that the next sentence is produced in the context.

## 4. Training and Generation

We train all the components in our hierarchical framework together from scratch with randomly initialized parameters. We treat the activation value indexed by a training

word  $w_t^n$  in the softmax layer of our sentence generator as the likelihood of generating that word:

$$P(w_t^n | s_{1:n-1}, w_{1:t-1}^n, \mathbf{V})$$

given 1) all the preceding sentences  $s_{1:n-1}$  in the paragraph, 2) all the previous words  $w_{1:t-1}^n$  in the same sentence  $n$ , and 3) the corresponding video  $\mathbf{V}$ . The cost of generating that training word is then defined as the negative logarithm of the likelihood. We further define the cost of generating the whole paragraph  $s_{1:N}$  ( $N$  is the number of sentences in the paragraph) as:

$$\begin{aligned} \mathcal{PPL}(s_{1:N} | \mathbf{V}) \\ = - \sum_{n=1}^N \sum_{t=1}^{T_n} \log P(w_t^n | s_{1:n-1}, w_{1:t-1}^n, \mathbf{V}) \Bigg/ \sum_{n=1}^N T_n \end{aligned}$$

where  $T_n$  is the number of words in the sentence  $n$ . The above cost is in fact the *perplexity* of the paragraph given the video. Finally, the cost function over the entire training set is defined as:

$$\mathcal{PPL} = \sum_{y=1}^Y \left( \mathcal{PPL}(s_{1:N_y}^y | \mathbf{V}_y) \cdot \sum_{n=1}^{N_y} T_n^y \right) \Bigg/ \sum_{y=1}^Y \sum_{n=1}^{N_y} T_n^y \quad (1)$$

where  $Y$  is the total number of paragraphs in the training set. To reduce overfitting, L2 and L1 regularization terms are added to the above cost function. We use Backpropagation Through Time (BPTT) [52] to compute the gradients of the parameters and Stochastic Gradient Descent (SGD) to find the optimum. For better convergence, we divide the gradient by a running average of its recent magnitude according to the RMSProp algorithm [43]. We set a small learning rate  $10^{-4}$  to avoid the gradient explosion problem that is common in the training process of RNNs.

After the parameters are learned, we perform the generation with Beam Search. Suppose that we use a beam width of  $L$ . The beam search process starts with the BOS (begin-of-sentence) symbol  $w_{\text{BOS}}$  (*i.e.*,  $w_0$ ) which is treated as a 1-word sequence with zero cost at  $t = 0$ . Assume that at any time step  $t$ , there are at most  $L$   $t$ -word sequences that were previously selected with the lowest sequence costs (a sequence cost is the sum of the word costs in that sequence). For each of the  $t$ -word sequences, given its last word as input, the sentence generator calculates the cost of the next word  $-\log P(w_t | w_{1:t-1}, \mathbf{V})$  and the sequence cost if the word is appended to the sequence. Then from all the  $t + 1$ -word sequences that are expanded from the existing  $t$ -word sequences, we pick the top  $L$  ones with the lowest sequence costs.

Of the new  $t + 1$ -word sequences, any one that is a complete sentence (*i.e.*, the last word  $w_{t+1}$  is the EOS (end-of-sentence) symbol  $w_{\text{EOS}}$ ) will be removed from the search

tree. It will be put into our sentence pool if 1) there are less than  $J$  ( $J \leq L$ ) sentences in the pool or, 2) its sequence cost is lower than one of the  $J$  sentences in the pool. In the second case, the sentence with the highest cost will be removed from the pool, replaced by the new added sentence. Also of the new  $t + 1$ -word sequences, any one that has a higher sequence cost than all of the  $J$  sentences in the pool will be removed from the search tree. The reason is that expanding a word sequence monotonically increases its cost. The beam search process stops when there is no word sequence to be expanded in the next time step. In the end,  $J$  candidate sentences will be generated for post-processing and evaluation.

After this, the generation process goes on by picking the sentence with the lowest cost from the  $J$  candidate sentences. This sentence is fed into our paragraph generator which reinitializes the sentence generator. The sentence generator then accepts a new BOS and again produces  $J$  candidate sentences. This whole process stops when the sentence received by the paragraph generator is the EOP (end-of-paragraph) which consists of only the BOS and the EOS. Finally, we will have a paragraph that is a sequence of lists, each list with  $J$  sentences. In our experiments, we set  $L = J = 5$ . Excluding the calculation of visual features, the average computational time for the sentence generator to produce top 5 candidate sentences with a beam width of 5 is 0.15 seconds, on a single thread with CPU Intel(R) Core(TM) i7-5960X @ 3.00GHz.

## 5. Experiments

### 5.1. Datasets

We evaluate our approach on two benchmark datasets: YouTubeClips [6] and TACoS-MultiLevel [35].

**YouTubeClips** This dataset consists of 1,967 short video clips (9 seconds on average) downloaded from YouTube. The video clips are open-domain, containing different people, animals, actions, scenarios, landscapes, *etc.* Each video clip is annotated with multiple parallel sentences by different turkers. There are 80,839 sentences in total, with about 41 annotated sentences per clip. Each sentence on average contains about 8 words. The words contained in all the sentences constitute a vocabulary of 12,766 unique lexical entries. We adopt the train and test splits provided by Guadarrama *et al.* [14], where 1,297 and 670 videos are used for training and testing respectively. It should be noted that while multiple sentences are annotated for each video clip, they are *parallel* and *independent* in the temporal extent, *i.e.*, the sentences describe exactly the same video interval, from the beginning to the end of the video. As a result, we use this dataset as a special test case for our approach, when the paragraph length  $N = 1$ .

**TACoS-MultiLevel** This dataset consists of 185 long

videos (6 minutes on average) filmed in an indoor environment. The videos are closed-domain, containing different actors, fine-grained activities, and small interacting objects in daily cooking scenarios. Each video is annotated by multiple turkers. A turker annotates a sequence of temporal intervals across the video, pairing every interval with a single short sentence. There are 16,145 distinct intervals and 52,478 sentences in total, with about 87 intervals and 284 sentences per video. The sentences were originally preprocessed so that they all have the past tense, and different gender specific identifiers were substituted with “*the person*”. Each sentence on average contains about 8 words. The words contained in all the sentences constitute a vocabulary of 2,864 unique lexical entries. We adopt the train and test splits used by Rohrbach *et al.* [35], where 143 and 42 videos are used for training and testing respectively. Note that the cooking activities in this dataset have strong temporal dependencies. Such dependency in a video is implied by the sequence of intervals annotated by a same turker on that video. Following Donahue *et al.* [11] and Rohrbach *et al.* [35], we employ the interval information to align our sentences in the paragraph during both training and generation. This dataset is used as a general test case for our approach, when the paragraph length  $N > 1$ .

## 5.2. Video Features

To model video object appearance, we use the pre-trained VggNet [39] (on the ImageNet dataset [37]) for both datasets. Since the objects in YouTubeClips are usually prominent, we only extract one VggNet feature for each entire frame. This results in only temporal attention in our sentence generator (*i.e.*,  $K = 1$  in Section 3.2). For TACoS-MultiLevel, the interacting objects are usually quite small and difficult to be localized. To solve this problem, both Donahue *et al.* [11] and Rohrbach *et al.* [35] designed a specialized hand detector. Once the hand regions are detected, they extract features in the neighborhood to represent the interacting objects. Instead of trying to accurately locate hands which requires a lot of engineering effort as in their case, we rely on a simple routine to obtain multiple object proposals. We first use Optical Flow [13] to roughly detect a bounding box for the actor on each frame. We then extract  $K$  image patches of size  $220 \times 220$  along the lower part of the box border, where every two neighboring patches have an overlap of half their size. Our simple observation is that these patches together have a high recall of containing the interacting objects while the actor is cooking. Finally, we compute the VggNet feature for each patch and pool all the patch features. When  $K > 1$ , the above routine leads to both temporal and spatial attention in our sentence generator. In practice, we find that a small value of  $K$  (*e.g.*,  $3 \sim 5$ ) is enough to yield good performance.

To model video motion and activities, we use the pre-

Table 1. Results on YouTubeClips, where B, M, and C are short for BLEU, METEOR, and CIDEr respectively.

trained C3D [44] (on the Sports-1M dataset [19]) for YouTubeClips. The C3D net reads in a video and outputs a fixed-length feature vector every 16 frames. Thus when applying the attention model to the C3D feature pool, we set  $K = 1$  and divide  $M$  by 16 (Section 3.2). For the TACoS-MultiLevel dataset, since the cooking activities are fine-grained, the same model trained on sports videos does not work well. Alternatively we compute the Dense Trajectories [50] for each video interval and encode them with the Fisher vector [17]. For the attention model, we set  $K = 1$  and  $M = 1$ .

## 5.3. Evaluation Metrics

We employ three different evaluation metrics: BLEU [34], METEOR [2], and CIDEr [45]. Because the YouTubeClips dataset was tested on by most existing video-captioning methods, the prior results of all the three metrics have been reported. The TACoS-MultiLevel dataset is relatively new and only the BLEU scores were reported in the previous work. We compute the other metrics for the comparison methods based on the generated sentences that come with the dataset. Generally, the higher the metric scores are, the better the generated sentence correlates with human judgment. We use the evaluation script provided by Chen *et al.* [7] to compute scores on both datasets.

## 5.4. Results on YouTubeClips

We compare our approach (h-RNN) on YouTubeClips with six state-of-the-art methods: LSTM-YT [47], S2VT [46], MM-VDN [53], TA [55], and LSTM-E [33]. To evaluate the importance of our video features, we also report the results of two baseline methods: h-RNN-Vgg and h-RNN-C3D. The former uses only the object appearance feature and the latter uses only the motion feature, with other components of our framework unchanged. The evaluation results are shown in Table 1. We can see that our approach performs much better than the comparison methods, in all the three metrics. The improvements on the most recent state-of-the-art method (*i.e.*, LSTM-E) are  $\frac{0.499 - 0.453}{0.453} = 10.15\%$  in the BLEU@4 score, and  $\frac{0.326 - 0.310}{0.310} = 5.16\%$  in the METEOR score. Although TA also employs tem-

	B@1	B@2	B@3	B@4	M	C

CRF-M [35]	0.584	0.467	0.352	0.273	0.272	1.347
LRCN [11]	0.593	0.482	0.370	0.292	0.282	1.534
h-RNN-Vgg	0.561	0.445	0.329	0.256	0.260	1.267
h-RNN-DT	0.557	0.451	0.346	0.274	0.261	1.400
RNN-sent	0.568	0.469	0.367	0.295	0.278	1.580
RNN-cat	0.605	0.489	0.376	0.297	0.284	1.555
h-RNN (Ours)	<b>0.608</b>	<b>0.496</b>	<b>0.385</b>	<b>0.305</b>	<b>0.287</b>	<b>1.602</b>

Table 2. Results on TACoS-MultiLevel, where B, M, and C are short for BLEU, METEOR, and CIDEr respectively.

poral attention, our approach produces much better results due to the fact that the hidden state of our RNN is not conditioned on the video features. Instead, the video features are directly input to our multimodal layer. Our approach also outperforms the two baseline methods by large margins, indicating that the video features are indeed crucial in the video captioning task.

## 5.5. Results on TACoS-MultiLevel

We compare our approach on TACoS-MultiLevel with three state-of-the-art methods: CRF-T [36], CRF-M [35], and LRCN [11]. Like above, we have two baseline methods h-RNN-Vgg and h-RNN-DT which use only the appearance and motion features respectively. We also add another two baseline methods RNN-sent and RNN-cat that have no hierarchy (*i.e.*, with only the sentence generator, but not the paragraph generator). RNN-sent is trained and tested on individual video clips that are segmented from the original 185 long videos according to the annotated intervals. The initial state of the sentence generator is set to zero for each sentence. As a result, sentences are trained and generated independently. RNN-cat initializes the sentence generator with zero only for the first sentence in a paragraph. Then the sentence generator maintains its state for the following sentences until the end of the paragraph. This concatenation strategy for training a paragraph has been exploited in a recent neural conversational model [48]. We use RNN-send and RNN-cat to evaluate the importance of our hierarchical structure.

The results on TACoS-MultiLevel are shown in Table 2. Our approach outperforms the state-of-the-art methods, including the very recently proposed one (*i.e.*, LRCN) with an improvement of  $\frac{0.305 - 0.292}{0.292} = 4.45\%$  in the BLEU@4 score. Given that our strategy of extracting object regions is relatively simple compared to the sophisticated hand detector used in the previous methods (Section 5.2), we expect to have even better performance if our object localization is improved. Our method is also superior to all the baseline methods. Although RNN-cat models temporal dependency among sentences by sentence-level concatenation, it performs worse than our hierarchical architecture. Again,

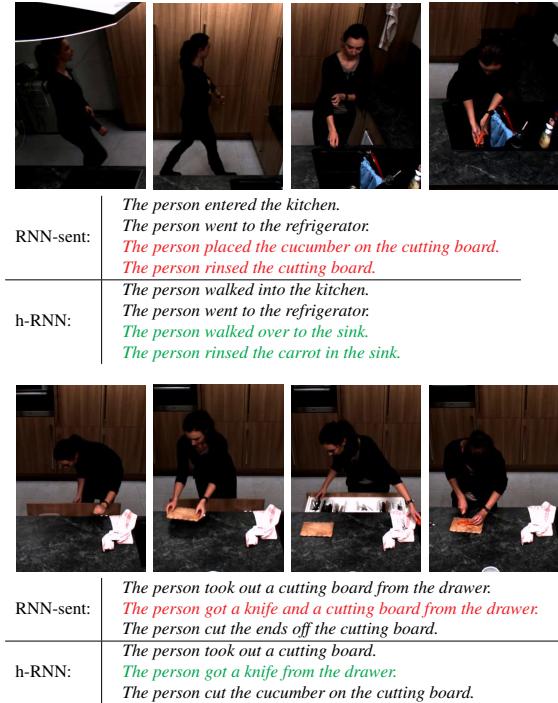

Figure 5. Examples of generated paragraphs. **Red** indicates incorrect sentences produced by RNN-sent and **green** shows the ones generated by our h-RNN in the corresponding time intervals. In the first example, our hierarchical model successfully captures the high likelihood of the event *walk to the sink* after the event *open the refrigerator*. In the second example, RNN-sent generates the event *take the cutting board* twice due to the fact that the sentences in the paragraph are produced independently. In contrast, our hierarchical model avoids this mistake.

it shows that both the video features and the hierarchical structure are crucial in our task. Figure 5 illustrates some example paragraphs generated by our approach on TACoS-MultiLevel.

## 5.6. Discussions and Limitations

Although our approach is able to produce paragraphs for video and has achieved encouraging results, it is subject to several limitations. First, our object detection routine has difficulty handling very small objects. Most of our failure cases on TACoS-MultiLevel produce incorrect object names in the sentences, *e.g.*, confusing small objects that have similar shapes or appearances (*cucumber vs. carrot*, *mango vs. orange*, *kiwi vs. avocado*, etc.). See Figure 1 for a concrete example: *sliced the orange* should really be *sliced the mango*. Accurately detecting small objects (sometimes with occlusion) in complex video scenarios still remains an open problem. Second, the sentential information flows unidirectionally through the paragraph recurrent layer, from the beginning of the paragraph to the end, but not also in the reverse way. Misleading information will be

potentially passed down when the first several sentences in a paragraph are generated incorrect. To address this issue, a bidirectional RNN [38, 51] could be used instead. Lastly, our approach suffers from a known problem as in most other image/video captioning methods, namely, there is discrepancy between the objective function used by training and the one used by generation. The training process predicts the next word given the previous words from groundtruth, while the generation process conditions the prediction on the ones previously generated by itself. This problem is amplified in our hierarchical framework where the paragraph generator conditions on groundtruth sentences during training but on generated ones during generation. A potential cure for this would be adding Scheduled Sampling [4] into the training process, where one randomly selects between the true previous words and the words generated by the model.

## 6. Conclusion

We have proposed a hierarchical Recurrent Neural Network framework for video paragraph captioning. The framework consists of a sentence generator and a paragraph generator. The paragraph generator models inter-sentence dependency to guide the sentence generator which produces short sentences given video data. The experiments show that our approach is able to generate multiple sentences or a paragraph for a long video and achieves the state-of-the-art results on two large-scale datasets.

## Acknowledgments

The primary author would like to thank Baidu Research for providing the summer internship and also the fellow interns for their helpful discussions.
